Abstract

In the tip-growing filamentous cell of the xanthophycean alga *Vaucheria terrestris* sensu Götz, a new growing tip develops in the non-growing, cylindrical region of the cell that was exposed by local illumination. The present study examined changes in the strength and extensibility of the cell wall of the new growing tip and in the matrix components of the inner surface of the cell wall. The internal pressure required to rupture the cell walls decreased remarkably during the early to middle stages of growing tip development, but the cell wall hardly extended before rupture. In contrast, during the middle and late stages of development, cell walls were extended by internal pressure. Atomic force microscopy revealed that protease-resistant, fine granular matrix components were present only at the apical portion of a normal growing tip, and were absent in the non-growing cylindrical region. In the early and middle stages of new growing tip development, these matrix components appeared in the cell walls in patches. These results suggest that first cell wall strength decreases and then cell wall extensibility increases in the development of new growing tips, and that protease-resistant, fine granular matrix components may be involved in rendering a cell wall extensible.

Abbreviations: AFM Atomic force microscopy

Introduction

Growth and morphogenesis of plant cells involve the expansion of existing cell walls and the deposition of new cell wall material. Therefore, the mechanical properties of existing cell walls, such as extensibility and strength, are fundamental to controlling plant cell growth and morphogenesis. In fact, many biomechanical studies on the multicellular tissues of angiosperms have shown that growth rates of plant cells are correlated with cell wall extensibility (Masuda 1990; Kutschera 1991; Cosgrove 1993). It has been generally believed that the mechanical properties of cell walls in such plants are controlled by the modification of matrix components of the cell wall and changes in their interactions with the cellulose microfibril skeletal components (Carpita and Gibeaut 1993; Cosgrove 1997, 1999).

In tip-growing cells, where growth of the cylindrical cell is limited in the domed end of the cell, there have also been a number of reports concerning the mechanical properties of the cell wall in a variety of organisms (e.g., Haughton and Sellen 1969; Money and Hill 1997; Dumais et al. 2004). Mine and Okuda (2003) have studied cell wall extensibility in tip-growing cells of the giant-cellular xanthophycean alga *Vaucheria terrestris*. Their experimental technique applied pressure to the isolated cell wall from tip-growing regions by applying internal pressure to silicone oil filling in the cell wall sac. They found that the cell wall in the tip-growing region was extended most, whereas the cell wall in the mature, cylindrical region was hardly extended (Mine and Okuda 2003). Extensibility of the tip-growing region was highest at pH 8 but very poor in acidic environments. Treatment of the isolated cell wall with the protease subtilisin caused significant weakening of the cell wall, but the pH dependency of the cell wall

1
2
3
4
5 extensibility remained. These results imply the existence of two distinct factors
6
7 controlling the mechanical properties of the cell wall: one factor promoting cell wall
8
9 extensibility in a pH-dependent manner in the tip-growing region (extensibility factor),
10
11 and the other protease-sensitive factor maintaining cell wall strength (strength factor).
12

13 Parker et al. (1963) reported that the cell wall of *Vaucheria* consisted of layers of
14
15 randomly oriented cellulose microfibrils and hot water-extractable matrix polysaccharide
16
17 consisting mainly of glucose and some uronic acids. Recently, we reported the surface
18
19 structures of intact and protease-treated cell walls of *V. terrestris* using atomic force
20
21 microscopy (AFM) (Mine and Okuda 2006). Protease treatment of the cell wall caused
22
23 loss of matrix components that contained embedded cellulose microfibrils in the inner
24
25 surface and that covered microfibrils in the outer surface throughout the cell. However,
26
27 even after the enzymatic removal of a significant amount of matrix components, fine
28
29 granular components remained among microfibrils in the apical portion of the
30
31 tip-growing region of the cell. Based on these observations, we proposed that the
32
33 protease-degradable matrix components that embed and cover microfibrils throughout
34
35 the cell relate to the strength factor of the cell wall, and protease-resistant fine granular
36
37 matrix components in apical portion relate to the extensibility factor of the cell wall
38
39 (Mine and Okuda 2006).
40

41 On the other hand, the *V. terrestris* cell spontaneously forms branches by
42
43 producing new growing tips in mature, non-growing, cylindrical regions of the cell. In
44
45 this branch formation process, an area of cell wall in the cylindrical region mechanically
46
47 strong enough to bear high tensile stress generated by turgor pressure should be
48
49 transformed into the extensible cell wall that may develop into the growing tip. During
50
51 this transition of the cell wall from strong to extensible, alternation of the

1
2
3
4
5 above-mentioned factors controlling the cell wall extensibility and strength might occur.

6
7 Moreover, it has been reported that branch formation in this alga can be artificially
8
9 induced by irradiation with blue light on a limited region of the cell (Kataoka 1975;
10
11 Takahashi et al. 2001). This enables us to obtain cell wall samples from distinct stages of
12
13 branch formation and extensibility.

14
15 Here we examined the changes in the extensibility and strength of the cell wall
16
17 during branch formation in this alga, in order to clarify the role of the cell wall's
18
19 mechanical properties in the morphogenetic process. We measured the change in the
20
21 internal pressure required for the extension and rupture of cell walls isolated from the
22
23 region where the branch formation had been induced by blue light irradiation, as well as
24
25 the total extension and extension rate of the pressurized cell wall until rupture. In addition,
26
27 using AFM, we examined the fine structure of the inner surface of protease-treated cell
28
29 walls from the area of branch formation. This was to explore cell wall components related
30
31 to the restoration of the extensibility in the mature, non-growing cell wall.

3
4
5 was used for extension experiments. The proteolytic enzyme (P8038, Sigma; subtilisin
6
7 Carlsberg; Lot No. 21K1653) was suspended in the buffer (pH 7.0) at a concentration of
8
9 10 units mL⁻¹ for protease treatment of cell wall fragments.

10 11 12 Induction of branch formation

13
14
15
16 Branch formation was induced by irradiation of microscopic illuminating a limited region
17
18 on the cylindrical part of the cell using a similar method to that described by Takahashi et
19
20 al. (2001). Briefly, apical cell fragments 1.5 to 3 mm long were excised with scissors from
21
22 cultured thalli, transferred to fresh culture medium and cultured for two days in the same
23
24 conditions as the stock culture. Actively growing, non-branched regenerated cells were
25
26 selected and transferred into the illumination vessel filled with medium using a Pasteur
27
28 pipette. The illumination vessel was a rectangular container constructed of plastic plates,
29
30 with inner dimensions 50 mm wide, 40 mm long and 3 mm deep (Fig. 1). A glass plate (25
31
32 mm wide, 40 mm long, and 2 mm in height) was placed on the bottom of the chamber so
33
34 that cells were raised to the focal range of microscopic observation. On the top of the
35
36 plate, two parallel streaks of silicon grease had previously been drawn at a separation
37
38 about 1 mm. Cells were laid parallel to each other between the grease streaks and
39
40 immobilized by gently pressing a small piece of cover slip over the grease streaks. The
41
42 illumination vessel was then covered with a transparent plastic lid, sealed with silicon
43
44 grease and placed on the specimen stage of an Olympus BHA light microscope. Cells
45
46 were observed through the 20x objective.

47
48 A daylight filter LBD (Olympus) was inserted just above the microscope
49
50 illuminator on the microscope base and a slit formed by the edges of two razor blades was

Deleted: 1

Deleted: 24

1
2
3
4
5 positioned about 40 mm above the filter. The height of the condenser was adjusted so that
6
7 the slit image was in the focal plane of the cells. The width of the slit was adjusted so that
8
9 it was 0.2 mm in the microscopic image. The opening of the condenser diaphragm was set
10
11 at 2.5 as indicated on the adjustment ring. The tungsten lamp in the microscope was set at
12
13 7 V, as measured by the built-in voltmeter. The position of the illumination vessel was
14
15 adjusted so that the edge of the slit was perpendicular to the axis of the cells and at 2-4
16
17 mm from the cell apex. Except for the light path, the vessel was covered by a cardboard
18
19 enclosure to minimize irradiation from ambient light.

20
21 Takahashi et al. (2001) reported sequential changes in cell structure in the
22
23 irradiated region during branch formation. In the present study, branch formation was
24
25 divided into the following four stages (Fig. 2): (i) aggregation of
26
27 protoplasm—chloroplasts accumulate in the irradiated region resulting in thickening of
28
29 protoplasm; (ii) formation of a new growing tip with a transparent patch and slight
30
31 bulging of the cell surface at the patch; (iii) dome-like protrusion—the localized
32
33 expansion at the new growing tip which makes the protrusion of the cell surface almost
34
35 hemispherical; and (iv) extension of a new branch with a dome-like growing tip and
36
37 subsequent cylindrical basal region. Takahashi et al. found that the irradiation time
38
39 required for branch formation was variable. We irradiated cells continuously for 5 to 8 h
40
41 and then examined them under the microscope to determine their stage of branch
42
43 formation.

44
45
46 Extension experiment on isolated cell wall

47
48
49
50 After irradiation, cells were transferred into a plastic Petri dish containing fresh medium

Deleted: 1

Deleted: 24

1
2
3
4
5 and excised at 1 mm proximal to the irradiated region. The excised cell was tightly
6
7 knotted with a nylon thread (0.08 mm in diameter; gift of Toray Industries Inc., Tokyo,
8
9 Japan) 1 mm distal to the irradiated region and the apical cell wall portion distal to the
10
11 knot was removed. The knot was lifted out of the medium and the cell wall around the
12
13 knot was glued with a cyanoacrylate adhesive (Aron Alpha, Toagosei Co. Ltd., Tokyo,
14
15 Japan), then submerged back into the medium in order to harden the glue and seal that end
16
17 of the cell. The cell wall was isolated by squeezing out the protoplasm as previously
18
19 described (Mine and Okuda 2003). Removal of the protoplasm was sometimes
20
21 incomplete due to the complicated cell wall shape at the branch protrusion (as seen in Fig
22
23 4d), but such remnant protoplasm did not affect the mechanical properties of the isolated
24
25 cell wall. Isolated cell walls were further prepared for the extension experiment as in
26
27 Mine and Okuda (2003), except that bending of the glass needle was omitted. Briefly, a
28
29 glass needle filled with the experimental buffer (pH 8.0) and silicone oil (KF-96L-2CS, a
30
31 gift from Shin-Etsu Chemical Co. Ltd., Tokyo, Japan) was inserted into the other end of
32
33 the isolated cell wall and glued, and the inside of the glass needle was pressurized at 100
34
35 kPa to infiltrate the cell wall with the experimental buffer from inside to outside of the
36
37 cell wall and to fill the cell wall with the oil. Tensile stress was further applied by
38
39 increasing the internal pressure by 4 kPa s⁻¹ until the cell wall ruptured. We stopped
40
41 increasing the internal pressure at 800 kPa even when the cell wall did not rupture,
42
43 because of the upper limit of the pressure regulator.

44 In cell walls at branch formation stages (ii), (iii) and (iv), protrusion of the cell
45
46 surface at the new growing tip maintained its shape even after removal of protoplasm.
47
48 The cell wall was rotated so that a side view of the protrusion was obtained, using the 10x
49
50 objective under an inverted microscope (Zeiss Axiovert S 100). During the above

Deleted: 1

Deleted: 24

1
2
3
4
5 extension experiment, changes in the shape of the cell wall around the new growing tip
6
7 were recorded with time-lapse images at 1 s intervals with a CCD camera mounted on the
8
9 microscope controlled by a computer, as previously described (Mine and Okuda 2003).
10
11 Each video frame was transferred to a file of the software PowerPoint (version 97,
12
13 Microsoft Corporation, Tokyo, Japan) and the cell wall outline was traced. The length of
14
15 the trace was calculated using computer software (Scion Image, Scion Corporation,
16
17 Frederick, MD, USA). The total extension (% cell diameter) of the cell wall until rupture
18
19 was calculated as the difference between the perimeter length at the initial pressure (100
20
21 kPa) and that at the video frame just before cell wall rupture, divided by the diameter of
22
23 the cell at the initial pressure (Fig. 5). The extension rate (% cell diameter s⁻¹) was
24
25 calculated by subtracting the perimeter length in a video frame from that in the video
26
27 frame 2 s later, which was also divided by the diameter of the cell at the initial pressure,
28
29 and further dividing by two.
30
31

32 Observation of cell wall surface fine structure

33
34
35
36 After irradiation, cells that had reached any stage of branch formation were transferred
37
38 into fresh medium and cut at the proximal boarder of the irradiated region. Protoplasm
39
40 was squeezed out at the cut and the cell wall portion about 0.2 mm from the cut was
41
42 excised. The excised cell wall portion was turned inside out using a pair of heat-extended
43
44 glass tubes installed on a micromanipulator, as shown in Fig. 3. The cell wall portion was
45
46 then incubated in a protease solution prepared as above at 30°C for 24 h. The protease
47
48 treatment has been shown to partially remove the matrix components of the cell wall
49
50 (Mine and Okuda 2006). It was carried out in the present study to test for the presence of
51
52
53
54
55
56
57
58
59
60

1
2
3
4
5 protease-resistant, fine granular matrix components of the cell wall, which have been
6
7 previously found specifically in the apical portion of tip-growing region (Mine and
8
9 Okuda 2006). After enzymatic treatment, the cell wall fragments were washed with buffer,
10
11 immobilized on a glass cover slip pretreated with aqueous polyethyleneimine P-70
12
13 solution (Wako Pure Chemicals, Osaka, Japan; original 30% solution diluted 1:300 with
14
15 distilled water), and air-dried. The cover slips were mounted on the specimen holder of an
16
17 atomic force microscope (JEOL JSPM-4200, at the Industrial Technology Center of
18
19 Kochi Prefecture, Japan) equipped with a probe (OMCL-AC160TS, Olympus). The inner
20
21 surface of the cell walls in the irradiated region was observed with the microscope using
22
23 AC mode. Topographic images (512 x 512 pixels) were obtained by scanning a 5 x 5 μm
24
25 or 1 x 1 μm specimen area at a scanning speed 0.33 or 0.67 ms per pixel, respectively.
26
27 Other scanning conditions were unchanged from the preset conditions. For comparison,
28
29 the inner surface of protease-treated cell walls isolated from apical and cylindrical
30
31 portions of normal tip-growing regions of the cell were also examined as in the previous
32
33 study (Mine and Okuda 2006).
34
35

36 Results

37 Changes in cell wall extensibility during branch formation process

38
39
40
41
42
43
44 In cells at stage (i) of branch formation, rupture did not occur at 800 kPa in three of the
45
46 eight cell wall fragments isolated. The remaining five cell walls ruptured at an average
47
48 pressure of 760 kPa (Table 1). From stages (ii), (iii) and (iv), five cell walls for each stage
49
50 were tested. All cell walls ruptured, with the required pressure decreased gradually with
51
52

Deleted: 1

Deleted: 24

1
2
3
4
5 progression of the branch formation stage. The average pressure required for cell wall
6 rupture was 532.4 kPa at stage (ii), 460.8 kPa at stage (iii), and 455.6 kPa at stage (iv)
7 (Table 1). The differences between the average pressures at stages (i) and (ii) and between
8 the average pressures at stages (ii) and (iii) were statistically significant (Student's *t*-test;
9 $P < 0.01$).

10
11
12
13
14
15 Cell walls isolated from cells at stage (i) ruptured suddenly, and cell wall
16 extension was too small to measure at this stage. Cell wall extension notably increased as
17 the branch formation process proceeded. At stage (ii) (Table 1, Fig. 4a-c), the cell wall
18 extended 4.2% of the cell's diameter before rupture in average; the average extension at
19 stage (iii) was 15.5% (Table 1, Fig. 4d-f); and finally the cell wall at stage (iv) showed
20 25.4% extension in average (Table 1, Fig. 4g-i). In addition to the amount of extension,
21 the rate of extension also increased with further branch formation (Table 1).
22
23
24
25
26
27
28
29

30 Fine structure of cell wall surface in branch-induced cell region

31
32
33
34 The observations were carried out on cell wall specimens isolated from three different
35 cells at stage (i) of branch formation. Microfibrils densely crossed with each other and
36 arranged in random directions were observed (Fig. 7a, b), as was seen in the cell wall
37 from the basal, cylindrical portion of the tip-growing region of the cell (Fig. 6c, d).
38 However, in all areas examined (six areas in total) at stage (i), no matrix components,
39 including fine granular ones, were detected.
40
41
42
43
44
45

46 We further observed the fine structure of the inner surface of cell walls isolated
47 from two different cells for each of stages (ii) and (iii). Topographic images of the inner
48 surface of the cell walls at stage (ii) in the area of the bulge showed bright patches
49
50

Deleted: 1

Deleted: 24

1
2
3
4
5 indicating that the specimen surface are locally raised in these patches (Fig. 7c). Fine
6 granular matrix components were observed among cellulose microfibrils in some of these
7 patches (Fig. 7d). In the cell wall at stage (iii), fine granular matrix components were also
8 observed in some patches (Fig. 8a, b), but no matrix components were observed in other
9 areas (Fig. 8c, d). We were not successful in turning the cell wall in the elongated bulge at
10 stage (iv) inside-out, so the fine structure of the cell wall inner surface at this stage
11 remains to be observed.

19 Discussion

20
21
22
23
24 Using cell walls isolated from the normal tip-growing region of cells of *V. terrestirs*, we
25 have previously demonstrated that mechanical properties such as extensibility and
26 strength of the cell wall are related to cell growth pattern (Mine and Okuda 2003). In the
27 present study, changes in the mechanical properties of the cell wall during the branch
28 formation process were examined. Mature, non-extensible cell wall in the cylindrical
29 region of the cell was converted into young, extensible cell wall in the tip-growing region
30 of a newly formed branch. The pressure at which cell wall rupture occurred was initially
31 much higher than the pressure obtained from previous extension experiments (400 to 500
32 kPa) for cell walls isolated from the tip-growing region (Mine and Okuda 2003). The
33 rupture pressure significantly decreased until stage (iii) (Table 1, Fig. 4), which is similar
34 to the pressure (463 kPa) required for extension of the isolated cell walls from the
35 tip-growing region at a comparable rate (Mine and Okuda 2003).
36
37
38
39
40
41
42
43
44
45
46
47

48 As pointed out in Dumais et al. (2004), the tensile stress exerted on the cell wall
49 inflated by internal pressure is proportional to the internal pressure, inversely
50
51
52

Deleted: 1

Deleted: 24

1
2
3
4
5 proportional to the thickness, and roughly in inverse relation to the curvature of the wall.

6
7 It is probable that the wall becomes thinner in actively expanding regions than in
8
9 non-growing regions. Although we did not collect data on the local wall thickness, cell
10
11 wall thinning would increase the tensile stress remarkably in the cell-surface protrusion.
12
13 Moreover, cell wall rupture often occurred in the subapical region of the new growing
14
15 apex (Fig. 4f, 4j), where the meridional curvature was smaller than in other regions.

16
17 Similar subapical extension was also observed in the cell wall isolated from the growing
18
19 tip region (Mine and Okuda 2003). Measurement of local thickness and curvature of the
20
21 isolated cell wall, and of the local wall extension observed in the extension experiments,
22
23 will provide detailed information on the cell wall's mechanical properties during branch
24
25 formation.

26
27 On the other hand, cell wall extension until rupture significantly increased as the
28
29 branch formation proceeded and finally reached to about half of the amount measured in
30
31 the normal tip-growing region under a lower, stable pressure (48.8% cell diameter at 450
32
33 kPa; Mine and Okuda 2003). Moreover, the maximum extension rate also increased and,
34
35 in stage (iv), reached more than 2% of cell diameter s^{-1} , as also observed in the previous
36
37 study on the cell wall isolated from normal tip-growing region under stable pressure
38
39 (Mine and Okuda 2003). Thus, cell wall extensibility increased during the branch
40
41 formation process. This implies that the mechanical properties of the cell wall are related
42
43 to the rather complicated cell morphogenetic process in which the growing region is
44
45 newly produced in a previously non-growing region of the cell.

46
47 A number of cellular morphogenetic events where a new tip-growing region is
48
49 generated in previously non-growing cell surfaces are known. For example, in branch
50
51 formation in fungal hyphae and giant cellular algae, arrangement of cytoskeletons and

Deleted: 1

Deleted: 24

1
2
3
4
5 other intracellular structures specifically found in the branch forming regions have been
6 reported (Okuda et al. 1993; Riquelme and Bartnicki-Garcia 2004, Mouriño-Pérez 2006).
7
8 Root hair formation is another extensively investigated example (Carol and Dolan 2002).
9
10 In this case, localized cell protrusion occurs on the cell surface along the side of a
11 trichoblast that has been fully extended by diffuse growth in an earlier developmental
12 stage of the cell. Although the molecular mechanisms of root hair initiation are not fully
13 understood, physiological factors such as protein phosphatase and calcium ion (Biblikova
14 and Gilroy 2000), and the arrangement of the cytoskeleton (Baluška et al. 2000) that
15 could be related to the localization and initiation of root hair formation have been
16 investigated. There have also been studies relating root hair initiation and factors
17 affecting the cell wall's mechanical properties. Localized cell wall acidification, which
18 probably promotes wall extensibility, was reported to be necessary for root hair bulging
19 (Bibikova et al. 1998). Recently, an expansin (see below) expressed specifically in roots
20 was identified and shown to be required for root hair initiation (Kwasniewski and
21 Szarejko 2006). In *V. terrestris*, Takahashi et al. (2001) reported protoplasmic aggregation
22 accompanied by changes in the arrangement of cytoskeletons during stage (i) of branch
23 formation. The present study provides the first evidence of changes in cell wall strength
24 and extensibility following cytoskeletal changes in the branch formation.

40 The pressure at which the cell wall ruptured significantly decreased from stage
41 (i) to stage (ii) and from stage (ii) to stage (iii), but the decrease was not statistically
42 significant between (iii) and (iv). The average pressure required for cell wall rupture at
43 stage (i) (759.6 kPa) is still far greater than the turgor pressure in this alga (560 kPa)
44 calculated from the cell's osmotic pressure (0.23 Osm, personal communication from Dr.
45 Hironao Kataoka). But, the pressure became lower than this turgor pressure at stage (ii)

4
5 and subsequent stages (Table 1). In contrast, the amount of extension and maximum
6
7 extension rate increased from stage (ii) to stage (iv). This suggests that during early stages
8
9 of branch formation the cell wall is weakened without remarkable promotion of the
10
11 extensibility of the cell wall, probably resulting in the decrease in the threshold (yield)
12
13 stress for initial cell wall extension in the early stages. The present results also evoke the
14
15 question of why the turgor pressure does not rupture the cell wall in the tip-growing
16
17 region of the living cells. If the actual turgor pressure measured by more reliable methods
18
19 is also significantly lower than the rupture pressure of the isolated cell wall, the existence
20
21 of cell structures that protect the cell wall from rupture by excessive turgor should be
22
23 considered; these might resemble, for example, the helmet-like, rigid structure postulated
24
25 to exist in tip-growing hyphae (Money, 1997).

26
27 In our previous study on cell walls isolated from tip-growing regions of this alga
28
29 (Mine and Okuda 2003), the cell wall was weakened by a protease treatment throughout
30
31 the cell and radial expansion of the enzymatically weakened cell wall in the region near
32
33 the cylindrical region often occurred. These results suggest that such cell wall weakening
34
35 also occurs during the early stages of branch formation, enabling cell wall extension for
36
37 initial branch protrusion by turgor pressure. It is also known that a major part of the cell
38
39 wall matrix components is removed by protease treatment (Mine and Okuda 2006),
40
41 suggesting a close relationship between the protease-degradable matrix components and
42
43 the protease-sensitive strength factor of the cell wall. Therefore, observations of the fine
44
45 structure of the cell wall at these stages will provide useful information about the
46
47 occurrence of such structural modification of matrix components of the cell wall.

48
49 Both the total amount of extension and the maximum extension rate
50
51 continuously increased until stage (iv), implying that improvement of cell wall

Deleted: 1

1
2
3
4
5 extensibility continues even after stage (iii), where the decrease in yield stress has
6
7 apparently been completed. We have previously reported that the protease treatment used
8
9 in the present study weakened the cell wall without affecting pH-dependency of the cell
10
11 wall extensibility (Mine and Okuda 2003). We have also reported that the fine granular
12
13 matrix components remained among the microfibrils after protease treatment of the cell
14
15 wall inner surface of the apical portion of the tip-growing region in this alga (Mine and
16
17 Okuda 2006). Therefore, we conclude that these protease-resistant fine granular matrix
18
19 components are concerned with the factor controlling the pH-dependent extensibility of
20
21 the cell wall. The observation in the present study that the fine granular matrix
22
23 components were found in patches among microfibrils of the inner cell wall surface at
24
25 stages (ii) and (iii), where the cell wall extensibility was significantly promoted (Figs. 5,
26
27 7) supports this conclusion. Although technical problems precluded our ability to make
28
29 observations at later stages, these matrix components should come to occupy a larger area
30
31 in the tip of the protrusion in stage (iv) and later, since the protrusion finally forms a new
32
33 normal growing tip of the cell where the matrix components were present throughout its
34
35 apical portion (Mine and Okuda 2006; Fig. 6a, b in the present study).

36
37 In angiosperms, it has been reported that the extensibility of cell walls is
38
39 controlled by proteinous cell wall components, such as expansins (Cosgrove 1996),
40
41 xyloglucan endotransglycosylase (Nishitani 1997; Rose et al. 2002), and specific
42
43 cellulases (Park et al. 2003). Many of these molecules are believed to control cell wall
44
45 extensibility by affecting intermolecular binding of cellulose microfibrils with other
46
47 matrix components, such as xyloglucans. Therefore, it is reasonable to presume that such
48
49 cell wall components accumulate in spaces between microfibrils in growing cell regions.
50
51 To clarify the relationship between the matrix components and cell wall extensibility,

1
2
3
4
5 further morphological investigations are in progress by us on the matrix components,
6
7 including their distribution along cell wall sections and possible secretion processes from
8
9 the protoplasm into the cell wall, as well as histochemical identification of the
10
11 components.

Figure legends

Fig. 1.

Schematic drawing of illumination vessel used for induction of branch formation. The rectangular container made of a plastic base plate (B) and a frame (F) was filled with medium. *Vaucheria* cells (V) were laid parallel between two streaks of silicon grease (G) drawn on a glass plate placed on the bottom of the container and covered with a small cover slip (S). After covering with a transparent lid (T), light from the microscope lamp (L) that passed through a narrow slit made of two razor blades (R) irradiated the cells through the microscope's condenser (C). The opening of the slit and the position of the condenser were adjusted to illuminate a 200 μm -wide region in the plane of the cell. During branch formation, cells were observed through an objective lens (O)

Fig. 2.

Fig. 2a-d Schematic drawing of outlines of irradiated cell regions in the four stages of branch formation in *Vaucheria terrestris* recognized in the present study. **a** Stage (i). Protoplasm has accumulated in the irradiated region but there is no change in the shape of the cell surface. **b** Stage (ii). A new growing tip is formed, with slight bulging of the cell surface. **c** Stage (iii). A dome-like protrusion of the cell surface resulted from the localized expansion at the new growing tip. **d** Stage (iv). The protrusion grew further, becoming a new branch with a cylindrical basal region

Fig. 3

Fig. 3a, b Schematic drawing of how cell wall fragments were turned inside-out. Outside

Deleted: 24

of cell wall is shaded and inside is clear. **a** A glass needle with a larger tip diameter (NL) was inserted into the cell wall fragment (CW) through the initial cut end at the boarder of the irradiated region. The other end of cell wall was folded to close this end temporarily and immobilized by lightly pressing the tip of a second glass needle with a thinner tip (NS) from the opposite direction. **b** Unfolded portion of the cell wall fragment was inverted over the thinner-tipped needle by tucking up to the opposite side using a pig hair bristle from a paint brush. This resulted in the cell wall portion that included the irradiated region being turned completely inside-out, allowing direct access to the inner surface of the cell wall

Fig. 4

Fig. 4a-i Series of images of cell wall fragments isolated from cells at various stages of branch formation. The fragments were tensed by increasing internal pressure applied to the silicone oil filling the cell wall. **a-c** Cell wall fragment at stage (ii). **a** At 100 kPa. **b** 508 kPa. The cell wall perimeter had been extended by 2.7% of the initial cell diameter. **c** Cell wall rupture 1 s after Fig. 4b. The protrusion of the cell wall surface was slightly enlarged before rupture. **d-f** Cell wall fragment at stage (iii). **d** At 100 kPa. **e** 476 kPa. Extension was 9.0%. **f** Cell wall rupture 1 s after Fig. 4e. Cell wall was markedly extended before rupture. **g-i** Cell wall fragment at stage (iv). **g** At 100 kPa. **h** 476 kPa. Extension was 22.0%. **i** Cell wall rupture 1 s after Fig. 4h. Cell wall was extended more than in Fig. 4d, e. Scale bar (40 μ m) in Fig. 4a also applies to Fig. 4b-i
